

SUPPLEMENTAL CHAPTER 7

Other HTML5 Features

In this final chapter on HTML5, I explain how to use geolocation and local storage and demonstrate the use of in-browser dragging and dropping, as well as how to set up and use web workers and make use of cross-document messaging.

Strictly speaking, most of these features (like much of HTML5) aren't really extensions to HTML, because you access them with JavaScript rather than with HTML markup. They are simply technologies that are being embraced by browser developers and have been given the handy umbrella name of HTML5.

This means, though, that you need to have fully understood the JavaScript tutorial in this book in order to use them properly. That said, once you get the hang of them, you'll wonder how you ever did without these powerful new features.

Geolocation and the GPS Service

The Global Positioning System (GPS) service consists of multiple satellites orbiting the Earth whose positions are very precisely known. When a GPS-enabled device tunes into them, the different times at which signals from these various satellites arrive enable the device to quite accurately determine where it is; because the speed of light (and therefore of radio waves) is a known constant, the time it takes a signal to get from a satellite to a GPS device indicates the satellite's distance.

By noting the different times at which signals arrive from different satellites, which are in precisely known orbital locations at any one time, a simple triangulation calculation gives the device its position relative to the satellites within a few meters or less.

Many mobile devices, such as phones and tablets, have GPS chips and can provide this information. But some don't, others have them turned off, and others may be

used indoors where they are shielded from the GPS satellites and therefore cannot receive any signals. In these cases, additional techniques may be used to attempt to determine the device's location.

I should also caution you to consider the privacy implications of geolocation, especially if the coordinates are transmitted back to the server as part of an application's function. Any application that has geolocation functionality should have an explicit privacy policy. Oh, and by the way, technically geolocation is not actually in the HTML5 standard. In fact, it's a standalone feature defined by the W3C/WHATWG, but most people think of it as part of HTML5.

Other Location Methods

If your device has mobile phone hardware but no GPS chip, it may attempt to triangulate its location by checking the timing of signals received from the various communication towers with which it can communicate (and whose positions are very precisely known). If there are a few towers, this can get almost as close to your location as GPS. But where there's only a single tower, the signal strength can be used to determine a rough radius around the tower, and the circle it creates represents the area in which you are likely to be located. This could place you anywhere within a mile or two of your actual location, down to within a few tens of meters.

Failing that, there may be WiFi access points whose positions are known within range of your device, and since all access points have a unique identifying address called a Media Access Control (MAC) address, a reasonably good approximation of your location can be obtained, perhaps to within a street or two. This is the type of information that Google Street View vehicles have been collecting (some of which it has since been made to discard due to potential breaches of data privacy rights).

And if that fails, the Internet Protocol (IP) address used by your device can be queried and used as a rough indicator of your location. Often, though, this provides only the location of a major switch belonging to your internet provider, which could be dozens or even hundreds of miles away. But at the very least, your IP address can (usually) narrow down the country and sometimes the region you are in.

IP addresses are commonly used by media companies for restricting playback of their content by territory. However, it's a simple matter to set up proxy servers that use a forwarding IP address (in the territory that is blocking outside access) to fetch and pass content through the blockade directly to a “foreign” browser. Proxy servers are also often employed to disguise a user's real IP address or bypass censorship restrictions and can be shared across many users on a WiFi hotspot (for example). Therefore, if you locate someone by IP address, you can't be completely sure that you have identified the right location, or even country, and should treat this information as only a best guess.

Geolocation and HTML5

In Supplemental [Chapter 4](#), I briefly introduced HTML5 geolocation. Now it's time to look at it in depth, shown again in [Example 7-1](#).

Example 7-1. Displaying a map of your current location

```
<!DOCTYPE html>
<html>
  <head>
    <title>Geolocation Example</title>
  </head>
  <body>
    <script>
      if (typeof navigator.geolocation == 'undefined')
        alert("Geolocation not supported.")
      else
        navigator.geolocation.getCurrentPosition(granted, denied)

      function granted(position)
      {
        var lat = position.coords.latitude
        var lon = position.coords.longitude

        alert("Permission Granted. You are at location:\n\n"
          + lat + ", " + lon +
          "\n\nClick 'OK' to load Google Maps with your location")

        window.location.replace("https://www.google.com/maps/@"
          + lat + "," + lon + ",8z")
      }

      function denied(error)
      {
        var message

        switch(error.code)
```

```

    {
      case 1: message = 'Permission Denied'; break;
      case 2: message = 'Position Unavailable'; break;
      case 3: message = 'Operation Timed Out'; break;
      case 4: message = 'Unknown Error'; break;
    }

    alert("Geolocation Error: " + message)
  }
</script>
</body>
</html>

```

Let's walk through this code and see how it works, starting with the `<head>` section, which displays a title. The `<body>` of the document is made up entirely of JavaScript, which immediately starts by interrogating the `navigator.geolocation` property. If the value returned is undefined, then geolocation is not supported by the browser and an error alert window is popped up.

Otherwise, we call the `getCurrentPosition` method of the property, passing it the names of two functions: `granted` and `denied` (remember that by passing only the function names, we pass the actual function code, not the result of calling the function, which would be the case if the function names had parentheses attached):

```
navigator.geolocation.getCurrentPosition(granted, denied)
```

These functions appear later in the script and are for handling the two possibilities of permission to provide the user's location data: `granted` or `denied`.

The `granted` function comes first and is entered only if the data can be accessed. If so, the variables `lat` and `long` are given the values returned by the geolocation routines in the browser.

An alert window is then popped up containing details about the user's current location. When they click OK, the alert is closed and the current web page is replaced by one at Google Maps. It's passed the latitude and longitude returned from the geolocation call, using a zoom setting of 8. You can set a different zoom level by changing the value 8z to another numeric value followed by a z, at the end of the `window.location.replace` call.

Displaying the map is achieved with a call to `window.location.replace`. The result looks like [Figure 7-1](#).

Figure 7-1. Interactive map of user's location is displayed

If permission is denied (or there is another issue), an error message is displayed by the denied function, which pops up its own alert window to inform the user of the error:

```
switch(error.code)
{
  case 1: message = 'Permission Denied'; break;
  case 2: message = 'Position Unavailable'; break;
  case 3: message = 'Operation Timed Out'; break;
  case 4: message = 'Unknown Error'; break;
}

alert("Geolocation Error: " + message)
```

When a browser requests geolocation data from the host, it will prompt the user for permission. The user can grant or deny permission. Denial results in the *Permission Denied* state, *Position Unavailable* results when the user grants permission but the host system cannot determine their location, and *Timeout* happens when the user grants permission and the host attempts to get their location but the request times out.

There's also another error condition in which some platform and browser combinations allow the user to dismiss the permission request dialog without either granting or denying permission. This results in the application “hanging” while waiting for a callback to occur.

In previous editions of this book, I used to call the Google Maps API to embed a map directly within the web page, but the service now requires a unique API key that you must apply for yourself, and usage over a certain amount can incur a fee. This is why the example now simply generates a Google Maps link. If you'd like to embed Google Maps in your web pages and web apps, everything you need to know is on the [website](#). Of course, there are also many other mapping options, such as [Bing Maps](#) and [OpenStreetMap](#), that have APIs you can access.

Local Storage

Cookies are an essential part of the modern internet, because they enable websites to save on each user's machine small snippets of information that can be used for tracking purposes. This isn't as ominous as it sounds, because most of the tracking going on helps web surfers by saving usernames and passwords, keeping them logged in to websites and social networks such as Twitter, Facebook, and more.

Cookies can also locally save your preferences for the way you access a website (rather than having those settings stored on the website's server) or can be used to keep track of a shopping cart as you build up an order on an ecommerce website.

But yes, they can also be used more aggressively to track the websites you frequent and gain a picture of your interests to try to target advertising more effectively. That's why the [European Union](#) now "requires prior informed consent for storage or for access to information stored on a user's terminal equipment."

But, as a web developer, think how useful it might be to keep data on users' devices, especially if you have a small budget for computer servers and disk space. For example, you could create in-browser web apps and services for editing word processing documents, spreadsheets, and graphic images, saving all this data offsite on users' computers and keeping your server purchasing budget as low as possible.

And from the user's point of view, think about how much faster a document can be loaded up locally than from across the web, especially on a slow connection. Plus, there's more security if you know that a website is not storing copies of your documents. Of course, you can never guarantee that a website or web app is totally secure, and you should never work on highly sensitive documents using software (or hardware) that can go online. But for minimally private documents such as family photographs, you might feel more comfortable using a web app that saves locally than one that saves files to an external server.

Using Local Storage

The biggest problem with using cookies for local storage is that each cookie can save only a maximum of 4 KB of data. Cookies also have to be passed back and forth on every page reload. And, unless your server uses Transport Layer Security (TLS)

encryption—the more secure successor to the Secure Sockets Layer (SSL)—each time a cookie is transmitted, it travels in the clear.

But with HTML5, you have access to a much larger local storage space (typically between 5 MB and 10 MB per domain, depending on the browser) that persists over page loads and between website visits (and even after powering a computer down and back up again). Also, the local storage data is not sent to the server on each page load, and it can be cleared by the user, so you usually want to keep the data on the servers as well; otherwise the user may find their data gone and be upset, even if they were the one who cleared the data.

Local storage data is handled through key/value pairs. The key is the name assigned for referencing the data, and the value can hold any type of data, but it is saved as a string. All data is unique to the current domain, and for security reasons any local storage created by websites with different domains is separate from the current local storage and is not accessible by any domain other than the one that stored the data.

The localStorage Object

You gain access to local storage by means of the `localStorage` object. To test whether this object is available, query its type to check whether or not it has been defined, like this:

```
if (typeof localStorage == 'undefined')
{
    // Local storage is not available—tell the user and quit.
    // Or maybe offer to save data on the web server instead?
}
```

How you handle the lack of local storage being available will depend on what you intend to use it for, so the code you place inside the `if` statement will be up to you.

Once you've ascertained that local storage is available, you can start making use of it with the `setItem` and `getItem` methods of the `localStorage` object, like this:

```
localStorage.setItem('loc', 'USA')
localStorage.setItem('lan', 'English')
```

To later retrieve this data, pass the keys to the `getItem` method, like this:

```
loc = localStorage.getItem('loc')
lan = localStorage.getItem('lan')
```

Unlike saving and reading cookies, you can call these methods at any time you like, not simply before any headers have been sent by the web server. The saved values will remain in local storage until erased in the following manner:

```
localStorage.removeItem('loc')
localStorage.removeItem('lan')
```

Or, you can totally wipe the local storage for the current domain by calling the `clear` method, like this:

```
localStorage.clear()
```

Example 7-2 combines the preceding examples into a single document that displays the current values of the two keys in a pop-up alert message, which initially will be null. Then the keys and values are saved to local storage, retrieved, and redisplayed, this time having assigned values. Finally, the keys are removed, and then an attempt at retrieving these values is again made, but the returned values are once again null. **Figure 7-2** shows the second of these three alert messages.

Example 7-2. Getting, setting, and removing local storage data

```
<!DOCTYPE html>
<html>
  <head>
    <title>Local Storage</title>
  </head>
  <body>
    <script>
      if (typeof localStorage == 'undefined')
      {
        alert("Local storage is not available")
      }
      else
      {
        loc = localStorage.getItem('loc')
        lan = localStorage.getItem('lan')
        alert("The current values of 'loc' and 'lan' are\n\n" +
              loc + " / " + lan + "\n\nClick OK to assign values")

        localStorage.setItem('loc', 'USA')
        localStorage.setItem('lan', 'English')
        loc = localStorage.getItem('loc')
        lan = localStorage.getItem('lan')
        alert("The current values of 'loc' and 'lan' are\n\n" +
              loc + " / " + lan + "\n\nClick OK to clear values")

        localStorage.removeItem('loc')
        localStorage.removeItem('lan')
        loc = localStorage.getItem('loc')
        lan = localStorage.getItem('lan')
        alert("The current values of 'loc' and 'lan' are\n\n" +
              loc + " / " + lan)
      }
    </script>
  </body>
</html>
```

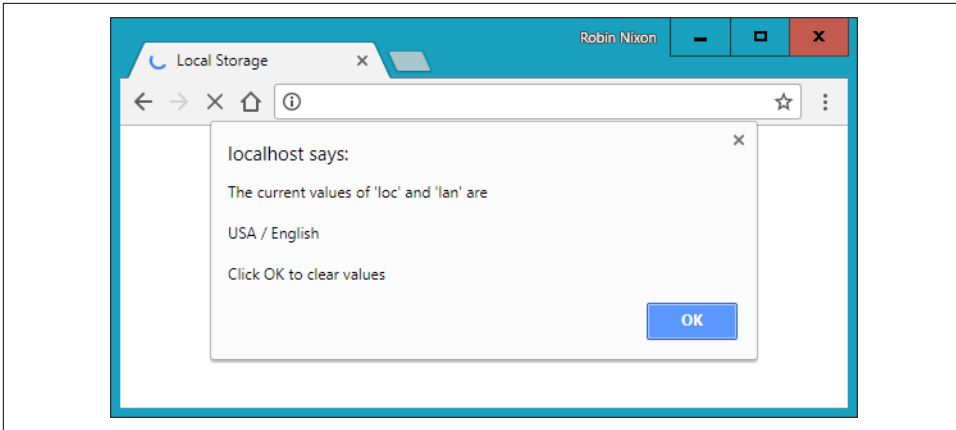

Figure 7-2. Two keys and their values are read from local storage

In local storage you can include virtually any and all data and as many key/value pairs as you like, up to the available storage limit for your domain.

Web Workers

Web workers run background jobs and are useful for calculations that take a long time and should not be allowed to hold the user back from doing other things. To use a web worker, you can create sections of JavaScript code that will run in the background. This code doesn't have to set up and monitor interrupts, as jobs have to do in some asynchronous systems. Instead, whenever it has something to report, your background process communicates with the main JavaScript through the use of an event.

This means the JavaScript interpreter gets to decide how to allocate time slices most efficiently, and your code only needs to worry about communicating with the background task whenever there's information to convey.

Example 7-3 shows how you can set up web workers to perform a repetitive task in the background—in this instance, calculating prime numbers.

Example 7-3. Setting up and communicating with a web worker

```
<!DOCTYPE html>
<html>
  <head>
    <title>Web Workers</title>
    <script src='OSC.js'></script>
```

```

</head>
<body>
  Current highest prime number:
  <span id='result'>0</span>

  <script>
    if (!!window.Worker)
    {
      var worker = new Worker('worker.js')

      worker.onmessage = function (event)
      {
        0('result').innerText = event.data;
      }
    }
    else
    {
      alert("Web workers not supported")
    }
  </script>
</body>
</html>

```

This example first creates a `` element with the ID of `result` in which output from the web worker will be placed. Then, in the `<script>` section, `window.Worker` is tested via a `!!` pair of not operators. This has the effect of returning a Boolean value of `true` if the `Worker` method exists and `false` otherwise. If it is not `true`, a message is displayed in the `else` section, alerting us that web workers are not available.

Otherwise, the program creates a new worker object by calling `Worker`, passing it the filename `worker.js`. Then the `onmessage` event of the new worker object is attached to an anonymous function that places any message passed to it by `worker.js` into the `innerText` property of the previously created `` element.

The web worker itself is saved in the file `worker.js`, whose contents are shown in [Example 7-4](#).

Example 7-4. The `worker.js` web worker

```

var n = 1

search: while (true)
{
  n += 1

  for (var i = 2; i <= Math.sqrt(n); i += 1)
  {
    if (n % i == 0) continue search
  }
}

```

```
    postMessage(n)
}
```

This file assigns the value 1 to the variable `n`. It then loops continuously, incrementing `n` and checking it for primality by a brute-force method of testing all values from 1 to the square root of `n` to see whether they divide exactly into `n`, with no remainder. Should a factor be found, the `continue` command stops the brute-force attack immediately because the number is not prime and starts processing at the next higher value of `n`.

But if all possible factors are tested and none result in a zero remainder, `n` must be prime, so its value is passed to `postMessage`, which sends a message back to the `onmessage` event of the object that set up this web worker.

The result looks like the following:

Current highest prime number: 30477191

To stop a web worker from running, issue a call to the `terminate` method of the worker object, like this:

```
worker.terminate()
```

If you wish to stop this particular example from running, you can enter the following into your browser's address bar:

```
javascript:worker.terminate()
```

Also note that due to the way Chrome handles security, you cannot use web workers on a filesystem, only from a web server (or running the files from *localhost* on a development server such as AMPPS, detailed in [Chapter 2](#)).

Web workers do have some security limitations that you should be aware of:

- Web workers run in their own independent JavaScript context and have no direct access to anything in any other execution context, including the main JavaScript thread or other web workers.
- Communication between web worker contexts is done via web messaging (`postMessage`).
- Because web workers have no access to the main JavaScript context, they cannot modify the DOM. The only DOM methods available to web workers are `atob`, `btoa`, `clearInterval`, `clearTimeout`, `dump`, `setInterval`, and `setTimeout`.

- Web workers are bound by the same-origin policy, so you can't load a web worker from a different origin than the original script without going through a cross-site methodology.

Drag and Drop

You can easily support dragging and dropping of objects on a web page by setting up event handlers for the `ondragstart`, `ondragover`, and `ondrop` events, as in [Example 7-5](#).

Example 7-5. Dragging and dropping objects

```
<!DOCTYPE HTML>
<html>
  <head>
    <title>Drag and Drop</title>
    <script src='OSC.js'></script>
    <style>
      #dest {
        background:lightblue;
        border      :1px solid #444;
        width       :320px;
        height      :100px;
        padding     :10px;
      }
    </style>
  </head>
  <body>
    <div id='dest' ondrop='drop(event)' ondragover='allow(event)'></div><br>
    Drag the image below into the above element<br><br>

    <img id='source1' src='image1.png' draggable='true' ondragstart='drag(event)'>
    <img id='source2' src='image2.png' draggable='true' ondragstart='drag(event)'>
    <img id='source3' src='image3.png' draggable='true' ondragstart='drag(event)'>

    <script>
      function allow(event)
      {
        event.preventDefault()
      }

      function drag(event)
      {
        event.dataTransfer.setData('image/png', event.target.id)
      }

      function drop(event)
      {
        event.preventDefault()
        var data=event.dataTransfer.getData('image/png')
```

```
        event.target.appendChild(0(data))
    }
</script>
</body>
</html>
```

After setting up the HTML, providing a title, and loading in the *OSC.js* file, this document styles the `<div>` element with the ID of `dest`, giving it a background color, border, set dimensions, and padding.

Then, the `<body>` section creates the `<div>` element and attaches the event handler functions `drop` and `allow` to the `ondrop` and `ondragover` events of the `<div>`. After this there's some text and then three images with their draggable properties set to `true`. The `drag` function is attached to the `ondragstart` event of each.

In the `<script>` section, the `allow` event handler function simply prevents the default action for dragging (which is to disallow it), while the `drag` event handler function calls the `setData` method of the `dataTransfer` object of the event, passing it the MIME type `image/png` and the `target.id` of the event (which is the object being dragged). The `dataTransfer` object holds the data that is being dragged during a drag-and-drop operation.

Finally, the `drop` event handler function also intercepts its default action so that dropping is allowed and then it fetches the contents of the object being dragged from the `dataTransfer` object, passing it the MIME type of the object. Then the dropped data is appended to the target (which is the `dest <div>`) via its `appendChild` method.

If you try this example for yourself, you'll be able to drag and drop the images into the `<div>` element, where they will stay, as shown in [Figure 7-3](#). The images cannot be dropped elsewhere, only into elements with `drop` and `allow` event handlers attached.

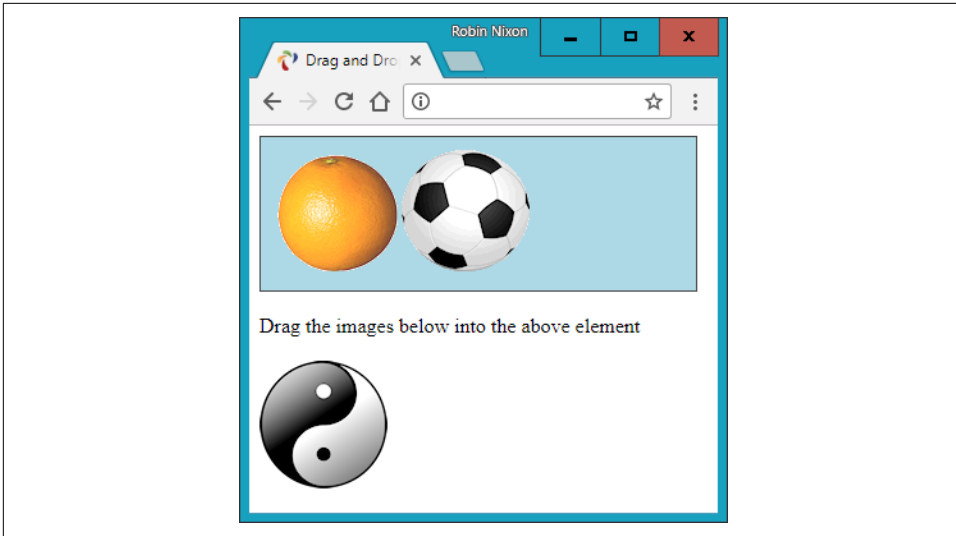

Figure 7-3. Two images have been dragged and dropped

Other events you can attach to include `ondragenter` (to run when a drag operation enters an element), `ondragleave` (to run when one leaves an element), and `ondragend` (to run when a dragging operation ends), which you can use, for example, to modify the cursor during these operations.

Cross-Document Messaging

You've already seen messaging in use a little earlier, in the web worker section. I didn't go into any details, however, as it wasn't the core topic being discussed, and the message was being posted only to the same document anyway. But for obvious security reasons, cross-document messaging does need to be applied with caution, so you need to fully understand its workings if you plan to use it.

Before HTML5, browser developers disallowed cross-document scripting, but in addition to blocking potential attack sites, this prevented communication between legitimate pages. Document interaction of any kind generally had to occur through Ajax and a third-party web server, which was cumbersome and fiddly to build and maintain.

But web messaging now allows scripts to interact across these boundaries by using some sensible security restraints to prevent malicious hacking attempts. It is achieved through use of the `postMessage` method, allowing plain-text messages to be sent from one domain to another, always within a single browser.

This requires that JavaScript first obtain the window object of the receiving document, letting messages post to a variety of other windows, frames, or iframes directly related to the sender's document. The received message event has the following attributes:

data

The incoming message

origin

The origin of the sender document, including the scheme, hostname, and port

source

The source window of the sender document

The code to send messages is just a single instruction, in which you pass the message to be sent and the domain to which it applies, as in [Example 7-6](#).

Example 7-6. Sending web messages to an iframe

```
<!DOCTYPE HTML>
<html>
  <head>
    <title>Web Messaging (a)</title>
    <script src='OSC.js'></script>
  </head>
  <body>
    <iframe id='frame' src='07.html' width='360' height='75'></iframe>

    <script>
      count = 1

      setInterval(function()
      {
        0('frame').contentWindow.postMessage('Message ' + count++, '*')
      }, 1000)
    </script>
  </body>
</html>
```

Here the usual use is made of the *OSC.js* file to pull in the 0 function, and then an `<iframe>` element with the ID of frame is created, which loads in [Example 7-7](#). Then, within the `<script>` section, the variable `count` is initialized to 1, and a repeating interval is set up to occur every second to post the string 'Message ' (using the `postMessage` method) along with the current value of `count`, which is then incremented. The `postMessage` call is attached to the `contentWindow` property of the `iframe` object, not the `iframe` object itself. This is important because web messaging requires posts to be made to a window, not to an object within a window.

Example 7-7. Receiving messages from another document

```
<!DOCTYPE HTML>
<html>
  <head>
    <title>Web Messaging (b)</title>
    <style>
      #output {
        font-family:"Courier New";
        white-space:pre;
      }
    </style>
    <script src='OSC.js'></script>
  </head>
  <body>
    <div id='output'>Received messages will display here</div>

    <script>
      window.onmessage = function(event)
      {
        O('output').innerHTML =
          '<b>Origin:</b>' + event.origin + '<br>' +
          '<b>Source:</b>' + event.source + '<br>' +
          '<b>Data:</b>' + event.data
      }
    </script>
  </body>
</html>
```

This example sets up a little styling to make the output clearer and then creates a `<div>` element with the ID `output`, in which the contents of received messages will be placed. The `<script>` section contains a single anonymous function attached to the `onmessage` event of the window. In this function, the `event.origin`, `event.source`, and `event.data` property values are then displayed, as shown in [Figure 7-4](#).

Figure 7-4. iframe has so far received 29 messages

Web messaging works only across domains, so you cannot test it by loading files in from a filesystem; you must use a web server (such as the AMPPS stack suggested

in [Chapter 2](#)). As you can see from [Figure 7-4](#), the origin is `http://localhost` because these examples are running on a local development server. The source is the window object, and the current message value is Message 29.

To run this for yourself, just load `06.html` into your browser using `localhost://` and not from a filesystem, and it will talk with `07.html` without you having to load it, because it is inserted into an `iframe`.

At the moment, [Example 7-6](#) is not at all secure because the domain value passed to `postMessage` is the wildcard `*`:

```
O('frame').contentWindow.postMessage('Message ' + count++, '*')
```

To direct messages only to documents originating from a particular domain, you can change this parameter. In the current case, a value of `http://localhost` would ensure that only documents loaded from the local server will be sent any messages:

```
O('frame').contentWindow.postMessage('Message ' + count++, 'http://localhost')
```

Likewise, as it stands, the listener program displays any and all messages it receives. This is also not a very secure state of affairs, because malicious documents also present in the browser can attempt to send messages that unwary listener code in other documents might otherwise access. Therefore, you can restrict the messages your listeners react to by using an `if` statement, like this:

```
window.onmessage = function(event)
{
  if (event.origin) == 'http://localhost')
  {
    O('output').innerHTML =
      '<b>Origin:</b> ' + event.origin + '<br>' +
      '<b>Source:</b> ' + event.source + '<br>' +
      '<b>Data:</b> ' + event.data
  }
}
```

If you always use the proper domain for the site you are working with, your web messaging communications will be more secure. However, be aware that since messages are sent in the clear, there may be insecurities in some browsers or browser plug-ins that might make this kind of communication insecure. One way to boost your security, then, is to use an encryption scheme for all your web messages and also consider introducing two-way communication protocols to verify each message as being authentic.

Normally, you won't alert the user to the `origin` or `source` values and will simply make use of them for security checking. These examples, however, display those values to help you experiment with web messaging and see what is going on. Instead

of using iframes, documents in pop-up windows and other tabs may also talk to each other using this method.

Other HTML5 Tags

A number of other new HTML5 tags are being adopted by the major browsers, including `<article>`, `<aside>`, `<details>`, `<figcaption>`, `<figure>`, `<footer>`, `<header>`, `<hgroup>`, `<mark>`, `<menuitem>`, `<meter>`, `<nav>`, `<output>`, `<progress>`, `<rp>`, `<rt>`, `<ruby>`, `<section>`, `<summary>`, `<time>`, and `<wbr>`. You can get more information on these and all other HTML5 tags from eastmanreference.com.
